ABSTRACT

Background: Proteinuria is a major component of preeclampsia. Urine protein measurement after 24 hour urine collection is the traditional standard method for the detection of proteinuria. It is time consuming. As an alternative, random spot sampling for a urine protein to creatinine ratio has been investigated. Objective: Screening for preeclampsia by urine albumin to creatinine ratio. Methods: The study was conducted on 202 antenatal women with gestational age 16-18 weeks. Specimens for measuring protein to creatinine ratio are obtained. Urine albumin was estimated by Bromocresol green assay and urine creatinine level was estimated by modified Jaff’s reaction. Urinary albumin to creatinine ratio of 0.2 or more was considered to be abnormal. Results: Out of 202 women 30 women had urine albumin creatinine ratio > 0.2 and 12 (40%) developed preeclampsia while out of 160 women with urine albumin to creatinine ratio <0.2 only 4 (2.5%) developed preeclampsia. The sensitivity, specificity, positive predictive value and negative predictive value of the test were 75%, 89.6%, 40% and 97.5% respectively. Conclusion: Spot urinary albumin to creatinine ratio is a reasonable rule out test for significant proteinuria. The Albumin to creatinine ratio is highly predictive to detect proteinuria and can be used as a rapid alternative test.

Keywords: Preeclampsia, proteinuria, albumin, creatinine.

Preeclampsia is a pregnancy specific multisystem disorder of unknown etiology that is characterized by development of hypertension and proteinuria after 20 weeks of gestation. Preeclampsia is regarded as severe if hypertension is accompanied by massive proteinuria (>5g/day) 1. An increase in total protein or albumin excretion is considered to be a sign of aggravation of preeclampsia, reflecting severe nephropathy. The 24 hours urine collection for protein is the gold standard in the diagnosis of preeclampsia.2 This method is time consuming, inconvenient and results may be inaccurate hence collection of urine is missed, depending upon the individual. An alternative method is to use the random albumin creatinine ratio. The protein to creatinine ratio of a single urine sample correlates with 24 hours protein excretion. In the presence of a stable glomerular filtration rate, urinary creatinine is excreted at a fairly constant rate3, which makes it useful as an internal reference. The usefulness of this method for assessing proteinuria in a non pregnant population is substantiated in the literature4. The international society for study of hypertension in pregnancy (ISSHP) has accepted spot urine protein to creatinine ratio as a method for identification of significant proteinuria (>300 mg in 24 hours).5 A protein

to creatinine ratio of <0.2 rules out significant proteinuria. The aim of this study is to observe urine albumin to creatinine ratio in preeclampsia.

**Method**

The study was done on 202 antenatal women between 16-18 weeks of gestation in M.L.N. Medical College. The study was certified by local ethics committee and informed valid consent was obtained from the participants. A detailed clinical history was taken and thorough clinical examination was done. Women with history of diabetes, chronic nephritis, essential hypertension, steroid use and collagen vascular diseases were excluded from the study. Apart from routine antenatal investigations urine albumin and creatinine ratio was done. Spot midstream urine specimen as obtained. Urinary albumin was estimated by Bromocresol green assay. This assay is based on the principle that at pH 3.68 albumin acts as a cation and binds to the anionic dye Bromocresolgreen forming a green coloured complex. The absorbance of final colour is measured at 630 nm. The colour intensity of the complex is proportional to albumin concentration in the sample.

Albumin (g/dl) = \( \frac{\text{Absorbance of test}}{\text{Absorbance of standard}} \times 4 \)

Creatinine level was estimated by modified Jaff's reaction. Creatinine reacts with picric acid in an alkaline medium to form an orange coloured complex. The rate of formation of this complex is measured by reading the change in absorbance at 505 nm in a selected interval of time and is proportional to the concentration of creatinine.

Creatinine (mg/dl) = \( \frac{\text{AT}_2 - \text{AT}_1}{\text{AS}_2 - \text{AS}_1} \times \text{dilution factor} \)

\( \text{AT}_1 = \text{Initial absorbance of test}; \)
\( \text{AT}_2 = \text{Final absorbance of test}; \)
\( \text{AS}_1 = \text{Initial absorbance of standard} \)
\( \text{AS}_2 = \text{Final absorbance of standard} \)

An urine albumin and creatinine ratio of > 0.2 was taken as abnormal. All cases were followed throughout pregnancy and monitored for development of preeclampsia. The performance of spot urine albumin to creatinine ratio in predicting proteinuria as calculated in terms of sensitivity, specificity, positive predictive value and negative predictive value.

**Results**

Out of 202 women, 30 showed albumin creatinine ratio > 0.2 and 12 (40%) developed preeclampsia whereas out of 16 women who had albumin creatinine ratio < 0.2 only 4 (25%) developed preeclampsia while majority 156 (97.5%) remained normotensive (Table 1 & 2). Urine albumin and creatinine ratio in a random sample had sensitivity 75%, specificity 89.6%, positive predictive value 40 %, and negative predictive value 97.5% in previous studies. The results of the present study are compared with those of previous studies (Table 3).

prediction of preeclampsia.

Discussion

Proteinuria is one of the diagnostic criteria of preeclampsia. The gold standard method of 24 hours urine protein estimation is cumbersome and time consuming. Dipstick method of evaluating proteinuria is not perfectly correlated. With negative to trace dipstick results; 66% women will have proteinuria > 300 mg in 24 hours. The protein to creatinine ratio of a single urine sample correlates significantly (p<0.001) with 24 hour protein excretion (Risberg et al)⁶. In the study by Demirci O et al⁷ (2014) protein to creatinine ratio had a good correlation with 24 hour protein excretion (r²: 0.758) in agreement with other studies⁸-¹¹. In accordance with the present study Robert et al¹², Rodrigues et al¹³, Papanna et al¹⁴ have shown high sensitivity, specificity and negative predictive value but in contrast to the low positive predictive value of the test (40%) detected in present study; they had shown a high positive predictive value for the test (Table 3). In the study by A K Wikstrom (2006)¹⁵ significant relationship as identified p<0.01 between random albumin creatinine ratio and 24 hour urine albumin level but correlation was poor with pearson correlation coefficient of 0.65 (r²: 0.42) but adjustment for maternal age and nifedipine medication significantly improved the correlation (r² : 0.60). In the ISSHP statement for classification and diagnosis of hypertensive disorders of pregnancy, random protein to creatinine ratio is claimed to be equivalent to total protein excretion in a 24 hour sample for diagnosing significant proteinuria. Also according to BJOG (2011), in early second trimester albumin to creatinine ratio predicted preeclampsia quite before the onset of clinical manifestations.

Conclusion

Determination of random protein to creatinine ratio could replace 24 hours urine collection as a simpler, faster method for the diagnosis of significant proteinuria and screening for preeclampsia.
